

Dencken Festival™

Spatial Condition System - a new kind of operating system for physical space

Concept Statement

Authored by CP Müller / Oddsized / Genboy / Dencken — Oddsized — May 2, 2026

Fractal spatial zones as a programmable reality layer: from game mechanics to real-world ambient computing.

A named area is any defined region of physical space.

An area is a spatial zone with a location, a boundary, an owner, and a set of properties that define its nature, role, and behavior. An area is an active object — not a passive annotation on a map, but an entity with form, function, and engagement rules.

What kind of entity it is, how it participates in the system, whether it is visible to others, who may interact with it, and under what governance it operates are all properties of the area object itself.

The system accommodates any configuration of area type, scope, and access model — from infrastructure-scale public network entities to ephemeral private zones that exist only around a single user, robot or device — without privileging any one configuration over another.

The Festival pattern

Areas may overlap, contain, or relate to other areas in any configuration and at any scale. They compose: an area inside another area inherits, extends, or overrides the behavior of its parent according to the rules of both. The depth of nesting is unlimited. Area owners can create multiple area networks for any purpose, enabling unified control and sharing area functions with other networks, inside or outside the spatial operating system.

Engagement by position.

Engagement with an area is determined by position. A participating device or robot maintains continuous awareness of its own location — through GPS, BLE, WiFi, or any available positioning method — and evaluates that position against the areas registered in the system.

This is a user-side tracking function, not a property of the area itself. The area does not watch. The participating device or robot resolves, at whatever frequency is appropriate, whether it is inside, outside, approaching, or moving through a given area, and reports that state to the system.

When a defined condition is met — derived from any combination of position, movement, time, presence, sensor state, or any other input the system can receive — a response is triggered. A condition may be as simple as crossing a boundary or as compound as any logical combination of observable states the user chooses to define. The set of possible conditions is not closed. It expands with the capabilities of devices, sensors, and data sources connected to the system. The system's role is to evaluate the conditions the user specifies, not to decide which conditions are meaningful.

When a condition is met, a response executes. A response is any action reachable from the system: a message, a command, a signal, an API call, a change in another area's behavior, an escalation to a controller — human or automated — or a chain of further conditions. Responses are not prescribed. The user authors them. The system executes them faithfully.

Differentiated layers of experience

Each area or area network carries a defined set of participants with assigned roles. The same condition in the same area may produce entirely different responses for different participants depending on their role and overlapping area's. This creates differentiated layers of experience and function within the same physical space, governed by the area's owner and whatever governance structure the area object specifies — centralized, decentralized, delegated, or autonomous.

The system is therefore not an application with a fixed feature set. It is a spatial programming environment: a general-purpose operational layer between the physical world and any connected system, in which users and organisations author the logic that governs their space. Its natural domains include but are not limited to security and access governance, ambient environment control, connected mobility, augmented and mixed reality, social and contextual identity, logistics, civic infrastructure, and any future domain in which location, condition, and response intersect.

Festival - From game mechanics to real-world ambient computing.

This mechanic was first implemented and publicly proven in the Festival plugin for Minecraft PocketMine-MP, authored and copyright-held by mr. Müller aka Genboy, with public releases dating from February 2018 (github.com/genboy/Festival). That sandbox demonstrated the stability and creative productivity of the core primitives under real user conditions. The transition to physical space requires only that the coordinate source and the response execution environment be real — the logic between them is identical.

The core claim

Any person or organisation should be able to define any area network, specify any condition within it, assign any response to that condition, govern who experiences what, and compose areas without limit — creating a user-authored, condition-responsive operational layer over physical reality that is open, general, and owned by its users, building user sovereignty over space.

Examples of solutions for security, automotive, social media, IOT, smart environments and Augmented Reality.

****Security****

Current access control is binary: you are in or out. Festival's model is fractal: you are in the lobby, or in the office, or in the server room, and each layer knows exactly who you are and fires a different set of consequences — logging, unlocking, alerting, changing camera modes, adjusting HVAC. No badge-swipe system today lets a user define their own sub-zones and attach their own triggers. Security teams spend millions building this from scratch. Your model makes it user-programmable.

****Automotive****

A car is an area. The driveway is an area inside the home area. The commute corridor is an area. The parking structure is an area. Right now, none of these talk to each other — the car doesn't know it's in your driveway versus a stranger's street. With Festival logic: entering the driveway area silences notifications, opens the garage, shifts the car into a comfort profile. Entering the city area adjusts suspension and route. Entering a school area triggers a speed governor. These aren't integrations —

they're consequences of being inside a zone, defined by the user, not the manufacturer.

****Social media and identity****

Every social platform today uses a single flat identity. Festival's whitelist-per-zone is the architecture for contextual identity — you are a different "you" in your neighborhood zone than in your workplace zone than in your festival-crowd area. The triggers aren't just device actions — they're who can see you, what profile you show, what content reaches you. Location-aware identity is the missing layer between surveillance social media and genuine human context-switching. Instagram Stories has a hint of this. Festival is the full model.

****IoT and smart environments****

Every smart home platform today treats the house as one area with switches. Festival fractal logic means: the house is an area, the living room is an area, your chair is an area. When you sit in your chair inside the living room inside the house, all three zone-enter events fire in sequence, and only your whitelist determines which ones you actually experience. That's not home automation — that's a programmable ambient environment that responds to the precise geometry of your presence. Then someone else enters your room.

****Augmented Reality****

AR has a content delivery problem: how do you know what to show where, and to whom? Festival solves both. The area defines *where*, the whitelist defines *to whom*, the triggers define *what*. A museum area shows an AR layer to general visitors. An inner zone for members shows deeper content. The artist's private area shows something no one else sees. You have built the permission model for spatial computing before spatial computing has a permission model.

This document establishes prior conception and authorship for the purpose of intellectual property record.
